Introduction

Inkjet printing has become an interesting tool since it allows precise and controlled deposition of various materials onto substrates, such as paper, ceramic, glass, and polymer foils. Typical inks are solutions of polymers or colloidal suspensions which contain particles or pigments with a certain size distribution.

An exciting application is the production of conductive tracks by inkjet printing, which can be printed directly from solution or suspension. A subsequent sintering step is necessary to render the tracks conductive. A typical ink is a suspension of noble metal nanoparticles, for example silver. The nanoparticles in the ink have a metal core and a polymeric shell, which stabilizes the particles to avoid agglomeration in the liquid phase. After printing the polymeric shell has to be removed which is done in the sintering step.

The conventional sintering method involves heating the sample at 220 °C for 60 minutes, which removes the dispersing agents. This allows the metal cores of the nanoparticles to touch and sinter together. As a result of the sintering mechanism, a continuous percolation network is formed that provides continuous channels for the conduction electrons to flow throughout the material without obstacles, therefore forming a low resistance pathway.

Figure 3. Scanning Electron Microscope images of printed silver tracks: unsintered nanoparticles (left) and sintered nanoparticles (right).

A suspension of silver nanoparticles in tetradecane (Nanopaste®) with Harima Chemical Ltd.) was inkjet printed using Microdrop’s Autodrop system, which is equipped with a ME-4-I400 dispenser system. The substrates used were polycarbonate, polyethylene terephthalate (PET).

Printed lines on polycarbonate were sintered for 3 minutes by microwave radiation using a monomodal microwave oven (Enmex Liberator, Biotage Monomodal Microwave System) operating at 2.45 GHz and a power of 300 W. The resistance per unit distance of the sintered lines was 6 to 6 GΩ cm and the resistivity of the material as calculated from the resistance and the cross-sectional area of a line is 30 x 10^-9 Ω m, which is 9% of the value of bulk silver (1.59 x 10^-8 Ω m).

Conclusions

We have successfully prepared conductive silver tracks by inkjet printing silver nanoparticles onto a polymer foil and by using microwave radiation to sinter these lines. We were able to use the microwave as a selective heating device, since conductive (silver) particles absorb microwaves to a better extent than polymer foil. Furthermore, the microwave was used to shorten the sintering time from 60 minutes down to 3 minutes. The resistance per unit distance of the sintered lines was 30 x 10^-9 Ω m.
